Abstract. The lower bound principle (introduced in Böhning and Lindsay (1988, *Ann. Inst. Statist. Math.*, **40**, 641–663), Böhning (1989, *Biometrika*, **76**, 375–383) consists of replacing the second derivative matrix by a global lower bound in the Loewner ordering. This bound is used in the Newton-Raphson iteration instead of the Hessian matrix leading to a monotonically converging sequence of iterates. Here, we apply this principle to the multinomial logistic regression model, where it becomes specifically attractive.

Key words and phrases: Kronecker product, Loewner ordering, lower bound principle, monotonicity.

1. Introduction

Let $L(\pi)$ denote the log-likelihood, $\nabla L(\pi)$ the score vector and $\nabla^2 L(\pi)$ the second derivative matrix at $\pi \in \mathbb{R}_m$. Suppose

$$(1.1) \quad \nabla^2 L(\pi) \geq B$$

for all π and some negative definite $m \times m$ matrix B . Here $C \geq D$ denotes Loewner ordering of two matrices and means that $C - D$ is non-negative definite. Consider the second order Taylor series for the log-likelihood at π_0 :

$$\begin{aligned} L(\pi) - L(\pi_0) &= (\pi - \pi_0)^T \nabla L(\pi_0) + \frac{1}{2} (\pi - \pi_0)^T \nabla^2 L(\pi_0 + \alpha(\pi - \pi_0)) (\pi - \pi_0) \\ &\geq (\pi - \pi_0)^T \nabla L(\pi_0) + \frac{1}{2} (\pi - \pi_0)^T B (\pi - \pi_0) \end{aligned}$$

where we have used (1.1) to achieve the lower bound for L . Maximizing the right-hand side of the above inequality yields the *Lower Bound* iterate $\pi_{LB} = \pi_0 - B^{-1} \nabla L(\pi_0)$. We have the following:

* Supplement to "Monotonicity of quadratic-approximation algorithms" by Böhning and Lindsay (1988). *Ann. Inst. Statist. Math.*, **40**, 641–663.

** This research was supported by the *German Research Foundation*.

THEOREM 1.1. (Böhning and Lindsay (1988)) (i) (*Monotonicity*) For the Lower Bound iterate we have

$$L(\pi_{LB}) \geq L(\pi_0) \quad \text{with} \quad ">" \quad \text{if} \quad \pi_{LB} \neq \pi_0.$$

(ii) (*Convergence*) Let (π_j) be a sequence created by the lower bound algorithm. If L is bounded above in addition, then

$$\|\nabla L(\pi_j)\| \xrightarrow{j \rightarrow \infty} 0.$$

2. Multinomial logistic regression

We observe vectors $Y = (y_1, \dots, y_{k+1})^T$, with $y_i = 0$ for all i besides one j with $y_j = 1$ and corresponding probability p_j , implying

$$EY = p, \quad \text{Cov } Y = \Lambda_p - pp^T, \quad \Lambda_p = \begin{pmatrix} p_1 & & 0 \\ 0 & \cdots & 0 \\ \vdots & & \vdots \\ 0 & & p_{k+1} \end{pmatrix}.$$

Recall that the *multinomial logit-model* is given by

$$p_i = \exp(\pi^{(i)T} \mathbf{x}) / \left[1 + \sum_{j=1}^k \exp(\pi^{(j)T} \mathbf{x}) \right] \quad \text{for } i = 1, \dots, k,$$

$$p_{k+1} = 1 / \left[1 + \sum_{j=1}^k \exp(\pi^{(j)T} \mathbf{x}) \right]$$

where $\mathbf{x} = (x_1, \dots, x_m)^T$ is the vector of covariates, and $\pi^{(i)}$ is the parameter vector corresponding to the i -th response category. For reasons of simplicity in presentation, consider the log-likelihood of just *one* observation Y :

$$\log \prod_{j=1}^{k+1} p_j^{y_j} = \sum_{j=1}^k y_j \pi^{(j)T} \mathbf{x} - \log \left[1 + \sum_{j=1}^k \exp(\pi^{(j)T} \mathbf{x}) \right].$$

Let $\pi = (\pi_1^{(1)}, \dots, \pi_m^{(1)}, \dots, \pi_1^{(k)}, \dots, \pi_m^{(k)})^T$ denote the mk -vector of mk parameters, the upper index going along with the response category, the lower index with the covariate. We have for the partial derivative

$$\frac{\partial L}{\partial \pi_g^{(h)}} = y_h x_g - \frac{\exp(\pi^{(h)T} \mathbf{x})}{1 + \sum_{j=1}^k \exp(\pi^{(j)T} \mathbf{x})} x_g = (y_h - \hat{p}_h) x_g$$

with the notation $\hat{p}_h = \exp(\pi^{(h)T} \mathbf{x}) / (1 + \sum_{j=1}^k \exp(\pi^{(j)T} \mathbf{x}))$. This yields the score vector

$$\begin{aligned} \nabla L(\pi) &= [(y_1 - \hat{p}_1)x_1, \dots, (y_1 - \hat{p}_1)x_m, \dots, (y_k - \hat{p}_k)x_1, \dots, (y_k - \hat{p}_k)x_m]^T \\ &= (Y - \hat{p}) \otimes \mathbf{x} \end{aligned}$$

where \otimes is the Kronecker product $A \otimes B$ of two arbitrary matrices. The observed information can be easily computed to be

$$\begin{aligned}
 & - \frac{\partial^2 L}{\partial \pi_{g'}^{(h')} \partial \pi_g^{(h)}} \\
 &= \frac{\delta_{hh'} \exp(\pi^{(h)T} \mathbf{x}) \left(1 + \sum_{j=1}^k \exp(\pi^{(j)T} \mathbf{x})\right) - \exp(\pi^{(h')T} \mathbf{x}) \exp(\pi^{(h)T} \mathbf{x})}{\left(1 + \sum_{j=1}^k \exp(\pi^{(j)T} \mathbf{x})\right)^2} x_{g'} x_g \\
 &= (\delta_{hh'} \hat{p}_h - \hat{p}_{h'} \hat{p}_h) x_{g'} x_g,
 \end{aligned}$$

leading to the observed information matrix

$$\begin{aligned}
 -\nabla^2 L &= \begin{pmatrix} \hat{p}_1(1 - \hat{p}_1)\mathbf{x}\mathbf{x}^T & -\hat{p}_1\hat{p}_2\mathbf{x}\mathbf{x}^T & \cdots & -\hat{p}_1\hat{p}_k\mathbf{x}\mathbf{x}^T \\ \vdots & \hat{p}_2(1 - \hat{p}_2)\mathbf{x}\mathbf{x}^T & & \vdots \\ -\hat{p}_k\hat{p}_1\mathbf{x}\mathbf{x}^T & \cdots & \cdots & \hat{p}_k(1 - \hat{p}_k)\mathbf{x}\mathbf{x}^T \end{pmatrix} \\
 &= (\Lambda_{\hat{\mathbf{p}}} - \hat{\mathbf{p}}\hat{\mathbf{p}}^T) \otimes \mathbf{x}\mathbf{x}^T.
 \end{aligned}$$

The proof of the following lemma is straightforward.

LEMMA 2.1. *If $A \leq B$ then for symmetric, nonnegative definite C :*

$$A \otimes C \leq B \otimes C.$$

LEMMA 2.2. $\Lambda_{\mathbf{p}} - \mathbf{p}\mathbf{p}^T \leq [E - \mathbf{1}\mathbf{1}^T/(k+1)]/2$, where $\mathbf{1}$ is the k -vector of 1's.

A proof of this lemma is given in the proof of Theorem 5.3 in Böhning and Lindsay (1988) or can be constructed from Theorem 2 in Baksalary and Pukelsheim (1985).

Taking Lemmas 2.1 and 2.2 together, we get the following main result:

THEOREM 2.1. (a) *For the information matrix of **one** observation we have:*

$$i(\pi) = (\Lambda_{\hat{\mathbf{p}}} - \hat{\mathbf{p}}\hat{\mathbf{p}}^T) \otimes \mathbf{x}\mathbf{x}^T \leq \frac{1}{2}[E - \mathbf{1}\mathbf{1}^T/(k+1)] \otimes \mathbf{x}\mathbf{x}^T.$$

(b) *For the information matrix of a **sample** of size n we get:*

$$\begin{aligned}
 i_{\text{com}}(\pi) &= \sum_{i=1}^n (\Lambda_{\hat{\mathbf{p}}_i} - \hat{\mathbf{p}}_i\hat{\mathbf{p}}_i^T) \otimes \mathbf{x}_i\mathbf{x}_i^T \leq \sum_{i=1}^n \frac{1}{2}[E - \mathbf{1}\mathbf{1}^T/(k+1)] \otimes \mathbf{x}_i\mathbf{x}_i^T \\
 &= \frac{1}{2}[E - \mathbf{1}\mathbf{1}^T/(k+1)] \otimes \sum_{i=1}^n \mathbf{x}_i\mathbf{x}_i^T \\
 &= \frac{1}{2}[E - \mathbf{1}\mathbf{1}^T/(k+1)] \otimes X^T X =: B,
 \end{aligned}$$

where X is the $n \times m$ design matrix $\begin{pmatrix} \mathbf{x}_1^T \\ \vdots \\ \mathbf{x}_n^T \end{pmatrix}$.

$$(c) \quad B^{-1} = 2[E - \mathbf{1}\mathbf{1}^T/(k+1)]^{-1} \otimes (X^T X)^{-1} = 2[E + \mathbf{1}\mathbf{1}^T] \otimes (X^T X)^{-1}.$$

$$(d) \quad \pi_{LB} = \pi_0 + B^{-1} \sum_{i=1}^n (\mathbf{Y}_i - \hat{\mathbf{p}}_i) \otimes \mathbf{x}_i.$$

Remark. Since $\sum_{i=1}^n (\Lambda_{\hat{\mathbf{p}}_i} - \hat{\mathbf{p}}_i \hat{\mathbf{p}}_i^T) \otimes \mathbf{x}_i \mathbf{x}_i^T = \sum_{i=1}^n (\Lambda_{\hat{\mathbf{p}}_i} - \hat{\mathbf{p}}_i \hat{\mathbf{p}}_i^T) \otimes \sum_{i=1}^n \mathbf{x}_i \mathbf{x}_i^T$ is *not* true in general, we would have to invert the $(mk)^2$ matrix i_{com} at each step of the Newton-Raphson iteration. If we have 6 response categories ($k = 5$) and $m = 10$ covariates, then i_{com} is a 50×50 matrix. In contrast, the lower bound principle needs to invert a 10×10 matrix *only once*. The lower bound algorithm converges linearly with convergence rate depending on $\|E - B^{-1} \nabla^2 L(\hat{\pi})\|$. If $\hat{\pi} = 0$, then the lower bound algorithm converges at least *superlinearly*. Thus, if $\hat{\pi}$ is “near” zero, the computational efficiency of the *lower bound iteration* can be expected to be better than that of the Newton-Raphson iteration. To evaluate this point, in Böhning and Lindsay ((1988), Section 5.1) a simulation experiment was undertaken for *binomial* logistic regression, that is $k = 1$. There, the comparison is essentially between inverting a $k \times k$ matrix *once* (the lower bound algorithm) and inverting it *several* times (until a stopping rule is met, for the Newton-Raphson iteration). In all cases studied there, the computational efficiency of the lower bound method was better than that of the Newton-Raphson iteration. However, a downward-tendency was observed when the difference in CPU-time was plotted against distance of $\hat{\pi}$ to zero. Thus, it is possible that in extreme cases the Newton-Raphson algorithm might be more efficient. Here, we are comparing the single inversion of a $k \times k$ matrix (in the lower bound algorithm) with several inversions of a $km \times km$ matrix (in the Newton-Raphson iteration). This feature makes the lower bound method specifically attractive.
